(Received 11 February 2015; accepted 23 March 2015; published online 10 April 2015)

We present here two promising techniques for the application of the complex network approach to continuous spatio-temporal systems that have been developed in the last decade and show large potential for future application and development of complex systems analysis. First, we discuss the transforming of a time series from such systems to a complex network. The natural approach is to calculate the recurrence matrix and interpret such as the adjacency matrix of an associated complex network, called recurrence network. Using complex network measures, such as transitivity coefficient, we demonstrate that this approach is very efficient for identifying qualitative transitions in observational data, e.g., when analyzing paleoclimate regime transitions. Second, we demonstrate the use of directed spatial networks constructed from spatio-temporal measurements of such systems that can be derived from the synchronized-in-time occurrence of extreme events in different spatial regions. Although there are many possibilities to investigate such spatial networks, we present here the new measure of network divergence and how it can be used to develop a prediction scheme of extreme rainfall events. © 2015 AIP Publishing LLC.

I. INTRODUCTION

Climate is as the brain a highly complex and high-dimensional system; both systems have a lot of joint properties, but there are also important distinctions. Understanding the mechanisms of climatic processes on all temporal and spatial scales is very difficult and even impossible in near future, but crucial for weather forecasts or assessment of long-term climate changes. A data-based investigation of the climate system is related with several challenges, in particular, non-stationarity (e.g., abrupt vs. slow changes), high-dimensionality, non-Gaussian distributed data (e.g., extreme events), natural vs. anthropogenic influences, etc.

A basic first step in data-based studies of such a complex high-dimensional system is reducing the dimensionality. The most widely used method for this is a decomposition into a very finite number of Empirical Orthogonal Functions (EOFs). This approach also allows to identify the main spatial patterns, such as large circulation patterns or teleconnections. However, the basis of the EOF approach is the covariance matrix, thus, only capturing the first two statistical moments and demanding for certain strict properties of the data, e.g., Gaussian distribution and stationarity.\textsuperscript{1} Even more obvious are constraints due to event-like data, as typical for rainfall and extreme events, or limitations by nonlinear interrelations. Moreover, the found EOFs do not undoubtedly coincide with typical climate phenomena.\textsuperscript{2}

Modern measurement techniques has allowed in the last decades to extend our knowledge into the past, leading to paleoclimatology. However, these data generate further challenges: Dating uncertainties and irregularly sampled time series are problems that limit the direct application of standard methods.

An alternative and novel approach for the study of different aspects of the climate system is related to the progress

in complex networks science in the past quarter century. At a first glance, it might appear surprising that the complex network approach can be used to analyse a continuous system as the climate and in particular, to identify spatio-temporal patterns in climate fields or regime shifts in the paleoclimate. However, the application of complex networks for climate analysis has become a lively and quickly progressive field in the last years. Although, this new approach is still in its infancy, first results are very promising and have already shown its impressive potential.

In the following, we will present two techniques based on complex networks, recurrence networks (Sec. III) and event synchronization (Sec. V), and will show how they can be used to uncover regime transitions in the paleoclimate by analyzing proxy records (Sec. IV) and to analyze spatiotemporal patterns of extreme rainfall leading to new prediction schemes (Sec. V). Finally, we summarize the potentials of this non-traditional approach, but discuss also open problems.

II. COMPLEX NETWORKS

We give here only a few basics on complex networks which will be used later (see, e.g., Refs. 3–5 for more detailed reviews on complex network analysis). A network is a set of nodes and links. We define a network as complex when its topology is highly irregular. A network can be defined by the adjacency matrix $A$. For undirected and unweighted networks, $A$ is a binary matrix, just indicating the existence of links between two nodes. In weighted networks, a link has a weight, i.e., $A$ consists of real numbers; $A$ is symmetric for undirected and asymmetric for directed networks. A network or its components (links, nodes) can be characterized by several measures. Here we mention only some selected measures.

The node degree in unweighted networks is simply the total number of links a node $i$ has and is given by the column sum of the adjacency matrix $A$

$$ k_i = \sum_j^N A_{ij}, \quad (1) $$

The distribution of this measure can be used to investigate, e.g., whether a network is scale-free. On directed networks, we can distinguish between the column-wise and raw-wise sums in Eq. (1) that give us the in- and out-degree, respectively. For weighted networks, the sum Eq. (1) becomes the so-called node strength, and for directed and weighted networks, we can consider the in- and out-strength

$$ S_{\text{in}}^i = \sum_{j=1}^N A_{ij} \quad \text{and} \quad S_{\text{out}}^i = \sum_{j=1}^N A_{ji}. \quad (2) $$

Another important measure is the transition coefficient

$$ T = \frac{\sum_{i,j,k=1}^N A_{ij} A_{jk} A_{ki}}{\sum_{i,j,k=1}^N A_{ij} A_{jk}}. \quad (3) $$

It measures the probability that the neighbors of a node are connected themselves.

III. RECURRENCE NETWORKS—A TIME SERIES ANALYSIS APPROACH BY MEANS OF COMPLEX NETWORKS

Analyzing time series by complex networks is a quite new idea that came up in the last decade. The generation of a complex network representation of a time series can be done using different approaches, e.g., by visibility graphs or temporal succession of local rank orders. A quite natural approach is to use the recurrence matrix of a dynamical system

$$ R_{ij} = \Theta(e - ||\tilde{x}(i) - \tilde{x}(j)||), \quad (4) $$

as the adjacency matrix of a complex network

$$ A = R - I \quad (5) $$

(with $I$ the identity matrix, $\Theta$ the Heaviside function, $\tilde{x}(i)$ a state at time $i = 1, \ldots, N$, and $N$ the number of state vectors). The recurrence matrix itself has become a basic tool of non-linear time series analysis and was first introduced by Eckmann et al. as recurrence plots that “are rather easily obtained aids for the diagnosis of dynamical systems.” Later this idea was extended by several quantification approaches leading to “an active field, with many ramifications we [Eckmann et al. –] had not anticipated.”

Fundamental works on such methodological developments have been published also in Chaos, e.g., on embedding issues and dynamical invariants, time-delay systems and non-chaotic strange attractors, heterogeneous recurrence analysis, or twin surrogates.

Because of the striking similarity between the recurrence matrix and the adjacency matrix (i.e., a binary and square matrix), the idea to identify the recurrence matrix with the adjacency matrix was so obvious that it came up almost at the same time (around 2008) within different research groups. Its main advantage is that the resulting recurrence network can be analyzed by the known network measures, i.e., further diagnostic tools become available for time series analysis. In particular, the transitivity coefficient $T$ is appropriate because it quantifies the geometry of the phase space trajectory and can be used to differentiate between different dynamics (e.g., regular and irregular). It also allows to define a dimensionality measure, the transitivity dimension

$$ D_T = \frac{\log(T)}{\log(3/4)}. \quad (6) $$

The quantification of the recurrence matrices can also be performed by the recurrence quantification analysis (RQA). In contrast to the network measures which describe the geometrical properties, the RQA measures characterize dynamical properties of the phase space trajectory. Therefore, the recurrence network based measures provide complementary information to the RQA and can, under certain circumstances, give more insights into the system’s behavior.

As a paradigmatic example, let us consider the Rössler system.
\[
\begin{align*}
\begin{pmatrix}
\frac{dx}{dt}, \frac{dy}{dt}, \frac{dz}{dt}
\end{pmatrix} &= (-y - z, x + ay, b + z(x - 35)),
\end{align*}
\] (7)

where we change the parameter \(a = b\) in a range where the system shows chaotic and periodic dynamics: \(a = 0.235, \ldots, 0.262\) (Figs. 1 and 2). Between \(a = 0.24\) and 0.25, the system does not have a positive Lyapunov exponent and generates periodic behavior (Fig. 3(a)).

A frequently used RQA measure for differentiating periodic and chaotic dynamics is the ratio of recurrence points that form diagonal lines in the recurrence plot, called determinism:

\[
\text{DET} = \frac{\sum_{i>j} n_{ij} P(l)}{\sum_{i>j} n_{ij}},
\] (8)

with \(P(l)\) the histogram of line lengths in the recurrence plot. The idea of this measure is that the length of a diagonal line in the recurrence plot corresponds to the time the system evolves very similar as during another time. Such repeated similar state evolution that is also related to predictability is typical for deterministic systems. In contrast, systems with independent subsequent values, like white noise, have mostly single points in the recurrence plot. DET is sensitive to transitions between chaotic and periodic dynamics in maps, but for continuous systems, such as our Rössler example, this measure fails for this task. For the entire range of the considered \(a\) values, it has very high values, close to one (Fig. 3(b), Table I). However, \(T\) shows increased values within the periodic window, close to a value of 3/4. In general, the network based measures, such as \(T\), can add further important aspects in recurrence analysis, in particular, for the uncovering of sudden changes of the dynamics.

**IV. IDENTIFICATION OF SUDDEN TRANSITIONS IN PALEOClimATE**

The recurrence network approach has great potential in different applications in many disciplines. Using as a classifier, it can help, e.g., to detect serious diseases, such as preeclampsia, to detect epileptic states, or to study multiphase fluid flows. Another important application is to detect critical transitions in the dynamics. Such transition detection is of crucial interest in studying variations of the past climate in order to better understand the climate system in general.

In the following, we discuss a typical example from paleoclimate research. The investigation of relationships between sea surface temperature (SST) and specific climate responses, like the Asian monsoon system or the thermohaline circulation in the Atlantic, as well as their regime changes, represents an important scientific challenge for understanding the global climate system, its mechanisms, and its related variability. Its better understanding is of crucial importance as non-linear feedback mechanisms and tipping points cause high uncertainty and an unpredictable future for humankind.

In paleoclimatology, different archives are used to reconstruct and study climate conditions of the past, as lake and marine sediments or speleothemes. Alkenone remnants in the organic fraction of marine sediments, produced by phytoplankton, can be used to reconstruct SST of
the past (alkenone paleothermometry), allowing to study the temperature variability of the oceans.\textsuperscript{39,40} Here, we will use a SST reconstruction for the South China Sea and the past 3 Ma derived from alkenone paleothermometry of the Ocean Drilling Programme (ODP) site 1143 (Ref.\textsuperscript{40}) (Figs. 4 and 5(a)). The South China Sea is strongly linked to the East Asian Monsoon system (EAM) that consists of a winter part with strong winds and a precipitation related summer part. In general, the East Asian Monsoon is of crucial importance for China’s socio-economic behavior, e.g., for agriculture or even for public health by its impact on prevalence of trace elements.\textsuperscript{41} The understanding of the mechanism is, therefore, crucial for learning about the past and the future climate and its impacts.

First we are faced with a typical problem in paleoclimatology because the original time series of ODP 1143 is not equally sampled. The sampling time ranges from 0.2 to 28 ka, with a median of 2.1 ka. If applying standard techniques (linear methods or classical RQA) then we would first need to interpolate the time series to an equidistant time axis. However, when using the recurrence network approach, the correct timing of the nodes is not so important (and could even be exchanged without changing the network properties), because it is characterizing the geometrical structure.\textsuperscript{32,42,43}

We calculate the recurrence networks and the transitivity coefficient \( T \) for sliding windows of length 410 ka (thus, with varying number of data points within the windows) and a moving step of 20 ka (Fig. 5). For the phase space reconstruction\textsuperscript{44} we choose an embedding dimension of \( m = 6 \) (as suggested by the false nearest neighbors method\textsuperscript{45}). The selection of the time delay is guided by the auto-correlation function and considered to be constant for all time windows to be approximately 20 ka (based on median sampling time

![FIG. 2. Network representation of the phase space reconstruction of the \( x \)-component of the Rössler system for (a) \( a = 0.245 \) and (b) \( a = 0.29 \). The network is constructed from the first 300 nodes of the recurrence matrix shown in Fig. 1 by a linear repulsion model. Node size and color can be used to represent selected node properties, here time (node color, the darker the larger \( t \)) and clustering coefficient (node size).]

Dramatic climate shifts are related with the Milankovich changes have appeared on regional but also global scale.  

In the last 3 Ma, several major and many smaller climate changes have appeared on regional but also global scale. Dramatic climate shifts are related with the Milankovich cycles and major changes in ocean circulation patterns. This transition is very well revealed by the significant increase of the EAM begun to be strongly coupled to global ice-volume change. During this time, the summer monsoon has weakened between 2.0 and 1.5 ka ago, a period of warm climate has end and the northern hemisphere glaciation started after 2.8–2.7 Ma. Based on thorough investigations of loess sediments, it is known that 1.25 Ma ago the intensity of the winter monsoon (as presented by the SST and for the considered time scale) shows lower values than during the previously discussed periods. The variation of the EAM began to be strongly coupled to global ice-volume change. This transition is very well revealed by the significant increase of between 2.8 and 2.2 Ma. Based on thorough investigations of loess sediments, it is known that 1.25 Ma ago the intensity of the winter monsoon (as presented by the SST and for the considered time scale) is to reconstruct a complex network from spatially embedded data) or grid points (e.g., when using model or reanalysis data). In unweighted networks, links represent high correlations between the time series belonging to the nodes, simply considered by applying a threshold on the interrelation matrix that could be, e.g., Pearson correlation  

\[
A_{ij} = \begin{cases} 
C_{ij} & \text{if } C_{ij} > T, \\
0 & \text{else.} 
\end{cases}
\]  

Such networks can be undirected or unweighted (as in Eq. (9)), but also directed or weighted.  

Within the climate context, such network approach has been applied to study, e.g., climate communities the impact of the El Niño/Southern Oscillation, major heat transport pathways and spatio-temporal scales, external and internal atmospheric forcing, to create early warning indicators of critical regime shifts or even for model inter-comparison. When using Pearson correlation for describing the interrelationships between the nodes, then the node degree is obviously related to the first EOF. Other network measures, such as betweenness centrality, provide further information that cannot be captured by the EOF analysis.  

In general, interrelationships between spatially located time series cannot be considered to be only linear. In order to examine nonlinear interrelations, information based measures (e.g., mutual information) were suggested for network reconstruction. In particular, when investigating climatological or meteorological phenomena, we often face event-like data, such as daily (or hourly) rainfall series or extreme events time series. For such kind of data, Spearman rank correlation could be used. However, an even more powerful approach for such data is the event synchronization approach.
Event synchronization was developed to investigate the synchronous activity of the neurons in the brain.\(^{58}\) It simply counts the number of temporally coinciding events in two event series \(x_1\) and \(x_2\) by allowing small deviations between the occurrences of the events, i.e., a dynamical delay between them. Let \(e_1(m)\) and \(e_2(n)\) be the time indices when events appear in \(x_1\) and \(x_2\) and \(m, n = 1, \ldots, l\) the number of a specific event (\(l\) is the total number of events in the event series). The waiting time between an event \(m\) in \(x_1\) and event \(n\) in \(x_2\) is \(d_{1,2}(m, n) = e_1(m) - e_2(n)\). If this waiting time \(d_{1,2}(m, n)\) is smaller than some dynamical delay \(\tau(m, n)\), the two events \(e_1(m)\) and \(e_2(n)\) are considered to occur synchronously. The dynamical delay \(\tau(m, n)\) is the half of the minimal waiting time of subsequent events in both time series around event \(e_1(m)\) and \(e_2(n)\) and not larger than a given maximal delay \(\tau_{\text{max}}, \text{i.e.,}\)

\[
\tau(m, n) = \min \left\{ \frac{d_{11}(m, m - 1), d_{11}(m, m + 1), d_{22}(n, n - 1), d_{22}(n, n + 1), 2\tau_{\text{max}}}{2} \right\}. \tag{10}
\]

As soon as \(|d_{1,2}(m, n)| \leq \tau(m, n)\) (or \(0 < d_{1,2}(m, n) \leq \tau(m, n)\)), we count it as undirected (or directed) synchronization of events \(e_1(m)\) and \(e_2(n)\)

\[
S(m, n) = \begin{cases}
1 & \text{if } |d_{1,2}(m, n)| \leq \tau(m, n) \\
0 & \text{otherwise, in the directed case}. \tag{11}
\end{cases}
\]

Now we can define the event synchronization \(E\) between the two event series as the sum of \(S(m, n)\)

\[
E = \sum_{m,n} S(m, n). \tag{12}
\]

This measure has the advantage that it can quantify interrelations between event-like time series and that it allows for a flexible (dynamical) delay between the events. This is particularly different from the standard approach, where a considered lag (e.g., for cross-correlation) is constant and fixed at each time point.

Applying the event synchronization approach, Eq. (12), for comparing spatially embedded time series \(x_i\) and \(x_j\) at locations (nodes) \(i\) and \(j\) a network can be reconstructed in the same way as in Eq. (9). For selecting the threshold \(T\) several approaches are possible. One possibility is based on a significance test, where block bootstrapping can provide an empirical test distribution of the values of \(E\) and a preselected confidence level (e.g., 2% or 5%) provides the threshold \(T\).\(^{70}\) This procedure ensures that the network links represent only the strongest interrelations between the nodes.

Event synchronization based complex networks have been successfully used to investigate spatio-temporal patterns during the Indian Summer monsoon\(^{44,69,71}\) or to study the origin and propagation of extreme rainfall in South America.\(^{70,72}\) Although there is an obvious dominance of climate applications, this approach is also promising for other fields, like plasma, turbulence, cardiological, or brain research.

\section*{VI. Developing a prediction scheme for extreme events}

To illustrate the potential of the complex network approach in the context of extreme climate events, we apply the approach on South American extreme rainfall data and use the network topology for developing a prediction scheme for extreme rainfall.\(^{70}\) During the Australian summer season (December, January, February), the differential heating between land and ocean amplifies the trade winds that enhance transport of moisture from the tropical Atlantic into the tropical Amazonian Basin, and thus, causes extended rainfall.\(^{73}\) Due to evapotranspiration, wind, and the Andean orographic barrier, this water is first further transported westwards, and later along the Andean mountain ridge, southwards towards the subtropics (Fig. 6). Here, a frontal system converging from the South and related with Rossby waves is responsible whether the moisture transport moves further eastward into the southeastern (SE) Brazil or towards the SE South America (SESA, central Argentinian plains).\(^{74}\) This variability of the exit moisture regions is also called South American rainfall dipole.\(^{75}\)

The spatio-temporal rainfall data used in our example are collected from the satellite-based Tropical Rainfall Measurement Mission (TRMM 3B42 V7, (Ref. 76)) with 3-hourly temporal and 0.25\(^{\circ}\) \(\times\) 0.25\(^{\circ}\) spatial resolution. In the following, we will restrict the analysis to the Australian summer season and consider extreme rainfall events that are defined locally by rainfall exceeding the 99th percentile.

Using directed event synchronization, Eqs. (11) and (12), of the rainfall extremes we reconstruct weighted and directed networks and calculate the in-strength \(S_i^{\text{in}}\) and out-strength \(S_i^{\text{out}}\), Eq. (2). Now we define the network divergence as the difference between in- and out-strength

\[
\Delta S_i = S_i^{\text{in}} - S_i^{\text{out}}. \tag{13}
\]

Negative values of \(\Delta S\) indicate the source regions of extreme events whereas positive values indicate sinks. Surprisingly, we find negative \(\Delta S\) values within the SESA region (Fig. 7).
This means that this region is a source region of extreme rainfall although it is one of the exit regions of the low-level moisture flow from the Amazon region. Now it would be interesting to see to which other places the extreme rainfall from the SESA region will propagate. For this purpose, we consider the in-strength of all nodes conditioned by the source region SESA and call it impact $I_i(R)$ of region $R$ on node $i$

$$I_i(R) := \frac{1}{|R|} \sum_{j \in R} A_{ij}, \quad (14)$$

$|R|$ is the number of nodes within the region of interest $R$ (here SESA). Casually speaking, $I_i(R)$ measures the amount of extremes at site $i$ that have their origin in region $R$.

For the SESA region, we find high values of $I_i(\text{SESA})$ not only in the direct vicinity of SESA but also at the eastern slopes of the Central Andes (Fig. 8). This result suggests that extreme rainfall at the Central (in particular, Bolivian) Andes will precede after rainfall events in the SESA region.

The mechanism behind this is an interplay between the orographic barrier, frontal systems approaching from the South, and the southward moisture flow from the Amazon basin resulting in the establishment of a wind channel attracting warm and moist air from the western Amazon region into the SESA region. Here, it collides with the cold air of the frontal system from the South and produces extended rainfall. This rainfall propagates together with the northern migration of the frontal system and is bounded in the West by the Andean orography.

This fact can be used for defining a simple but very efficient prediction scheme as explained in detail by Boers et al. The precondition is a low-pressure anomaly in the SESA (geopotential height anomaly $< -10$ m). As long as this condition is fulfilled, during two days extreme rainfall will appear at the eastern slopes of the Central Andes (in the range along the band that is marked by high values of $I_i(\text{SESA})$). This rule allows positive prediction rates of 60% and during El Niño conditions even of 90%.

FIG. 6. Key features of the South American monsoon system. The blue arrows indicate major moisture transport pathways.

FIG. 7. Network divergence $\Delta S$ of extreme rainfall network during Austral winter season. Negative values indicate source and positive values sink regions of extreme rainfall.

FIG. 8. Impact $I_i(R)$ of a region (here SESA, marked by the box) in form of contributing propagated extreme rainfall.
VII. CONCLUSION AND OUTLOOK

In this paper, we have presented an overview of a complex network based method for the analysis of continuous dynamical systems. These methods are mainly basing on two concepts: (i) recurrence networks and (ii) event synchronization. The first one combines recurrence, a basic principle in dynamical systems, with complex networks. This way a rich variety of complex networks characteristics become available for time series analysis. Its potential has been demonstrated for the identification of sudden transitions from even short time series. The second one identifies events occurring almost synchronized in time in different spatial regions and uses then complex networks for the study of especially spreading and interactions of extreme events. We have uncovered with this technique a mechanism for the formation of extreme floods in the Andes which has led to a very efficient framework for predicting such extreme events. Additionally, this methodology can be used as a new tool for a critical comparison of different models of, in particular, natural systems. Such complex network approaches have a strong potential for various fields, ranging from turbulence, via neuroscience and medicine to socio-economy.

However, there are several open problems to study in future. One direction is to extend these concepts to multivariate (spatio-temporal) data, e.g., different climatological or physiological parameters. A further challenge is the study of interacting systems of possible very different nature, e.g., climate and renewable energy generation or climate and health, from the network perspective. Another problem is a comprehensive mathematical foundation of these techniques including an appropriate test statistics. Thus, we expect a pursuing and lively development and an increasing number of applications of these rather new concepts in the next future.
